Abstract

Under Medicare Part D, people choose prescription drug insurance offered by many private insurers. We examine non-poor enrollees' actions in 2006 and 2007 using panel data. This population reduced overspending by nearly $300 on average, with gains by 81% of them. The greatest improvements were by those who overspent most in 2006 and by those who switched plans. Decisions to switch or stay depended on individuals' overspending in 2006 and on upcoming changes in their current plans. The oldest consumers and those initiating medications for Alzheimer's disease improved by more than average, suggesting that real-world institutions help overcome cognitive limitations.

Abstract

Under Medicare Part D, people choose prescription drug insurance offered by many private insurers. We examine non-poor enrollees' actions in 2006 and 2007 using panel data. This population reduced overspending by nearly $300 on average, with gains by 81% of them. The greatest improvements were by those who overspent most in 2006 and by those who switched plans. Decisions to switch or stay depended on individuals' overspending in 2006 and on upcoming changes in their current plans. The oldest consumers and those initiating medications for Alzheimer's disease improved by more than average, suggesting that real-world institutions help overcome cognitive limitations.

"The new Medicare Part D prescription drug insurance market illustrates that leaving a large block of uninformed consumers to sink or swim, and relying on their self-interest to achieve satisfactory outcomes can be unrealistic."

Nobel Laureate Daniel McFadden

2006 Presidential Address to the American Economic Association

1 Introduction

Medicare Part D stands at a remarkable crossroads of the current political and academic debates. Beginning in 2006, Part D expanded Medicare beneficiaries' access to prescription drug coverage by allowing them to choose among competing private insurance plans. The philosophy underlying this approach adopts the perspective that private competition within a regulated framework would strike the appropriate balance between cost control and providing value to consumers. Within Part D, costs are controlled through private insurers negotiating prices with pharmaceutical manufacturers in conjunction with demand-side cost-sharing such as copays and the "doughnut hole."[1] At the same time, competition for enrollees would incentivize insurers to design plans that were attractive to individuals. To limit adverse selection and encourage participation, the program provided large subsidies even to non-poor beneficiaries and penalties for those who did not enroll when they became initially eligible.[2]

Although many of the widely-publicized opinions of the program were initially pessimistic, the growing evidence from research on Part D is largely positive, with high participation, expanded prescription drug use, lower out-of-pocket prices for drugs, high consumer satisfaction, and total program costs below projections. One contentious remaining aspect of Part D is whether its reliance

---

[1]Consumers who do not receive federal low-income subsidies enter the "doughnut hole" and pay 100% of drug costs out of pocket once the total drug spending exceeds a threshold, and they exit it once their spending reaches another threshold. In 2006, these thresholds for the standard plan design were $2,250 and $5,100, respectively.

[2]Beneficiaries could avoid this penalty by immediately enrolling in a Part D plan, a Medicare Advantage plan, or an employer-sponsored plan meeting the creditable coverage criteria, which require the plan to have an actuarial value meeting or exceeding the regulated standard plan.

on competition between many private insurers is too complex for beneficiaries to navigate despite the program's regulation and subsidies.

Part D is an important context to study consumer choice due to the large number of lives and dollars involved. It offers an environment rich for testing theories of individual conduct that will inform policy in health care as well as other markets. Because of the age and prevalence of illness of the Medicare population, cognitive limitations may be common among this population. This may be compounded by the fact that prescription drug insurance plans are multiattribute, with some aspects uniform across individuals, such as premiums and deductibles, while others vary across individuals due to differences in prescription drug use in conjunction with plans' use of formularies. Finally, because this was a newly created market, all eligible beneficiaries confronted these complex choices for the first time in late 2005. This last feature is econometrically attractive because analyzing data that include 2006 overcomes the initial condition problem raised by Heckman (1981), allowing researchers to separate the effects of aging from the effects of experience.

Behavioral economists have reported a number of biases in consumer decision making, such as inertia and confusion, particularly when cognition is limited by age, illness, or limited attention, e.g., Lusardi, Mitchell, and Curto (2009) and Agarwal, Driscoll, Gabaix, and Laibson (2009). These contributions have raised a number of academic questions about how to best model and predict decision making. They also evoke calls for a number of regulatory reforms, such as stronger consumer protection rules and simplification of credit cards, mortgages, retirement plans and health insurance contracts. In Part D specifically, many observers have called for a reduction in the number of plans available to consumers, which ranged across regions from 27 to 52 plans available in 2006 and 45 to 66 available in 2007.[3] In fact, regulatory changes will limit the number

---

[3] Liebman and Zeckhauser (2008) perhaps best summarize the mistrust in consumers' ability to choose: "health insurance is too complicated a product for most consumers to purchase intelligently," they state, concluding that, "[i]t is unlikely that most individuals will make sensible decisions when confronted with these choices." Based on these premises they suggest that either a public agency or some private company should mediate consumers' health insurance purchases. Similarly, Hoadley (2008) surveys a panel of medical experts to call for a standardization of plan

of options that insurers can make available to consumers in 2011 (Hoadley, Cubanski, Hargrave, Summer, and Neuman (2010)).

In this article we present evidence about how consumers' actual plan choices in Medicare Part D evolve over time. To achieve this, we analyze a large, comprehensive data set that reports every individuals' chosen and available plans, prescription drug use and spending, and other characteristics in 2006 and 2007. Two existing articles also rely on large data sets, both finding that consumers inappropriately weight various attributes of the plans, causing them to choose plans that do not minimize their costs for drugs and drug insurance. In the first, Heiss, McFadden, and Winter (2007) conclude that enrollees' choices can be best understood as myopic, relying on static expectations and using only current drug expenditures. They find that beneficiaries appear to be rational in their decisions about whether to participate in Part D, but less so in their plan choices conditional on participation.

In the second article, Abaluck and Gruber (2009) conclude that enrollees show inconsistencies with optimizing behavior because they overweight some features of the plan, such as plan premiums and doughnut hole coverage, while neglecting others. They thus conclude that elders fail to make choices consistent with optimization under full information. Bolstering the conclusions of Abaluck and Gruber (2009), Kling, Mullainathan, Shafir, Vermeulen, and Wrobel (2009) conclude that older adults suffer from serious misperceptions of prices and other features of Part D plans. According to their evidence, people's misperceptions result in them choosing prescription plans that are substantially more expensive than the available alternatives. One implication is that greater choice and competition harms rather than improves welfare because plans can flourish

benefits and formularies to make them easier to compare as well as reducing the number of plans available. Hanoch, Rice, Cummings, and Wood (2009) reached the same conclusion after analyzing the experimental evidence of 192 subjects (half of whom were age 65 or older) who performed hypothetical enrollment decisions. Duggan, Healy, and Scott-Morton (2008), Goldman and Joyce (2008), Joyce, Goldman, Vogt, Sun, and Jena (2009) and Heiss, McFadden, and Winter (2009) are notable exceptions to the opinion of the majority of researchers in this area.

by promoting confusion rather than by designing products that meet fully-informed, unbiased consumers' preferences.

With the exception of Kling et al. (2009), these prior articles analyzed only 2006 and did not consider how consumers' actions changed over time. Yet in contrast to the often cross-sectional and typically laboratory-based evidence of common biases in consumer choice, summarized in DellaVigna (2009), other work suggests that markets and market experience ameliorate those biases, e.g., List (2003), List (2004), List (2006), and List and Millimet (2008).[4] Considering the dynamic aspects of consumer choice is important to evaluate Part D given the large degree of heterogeneity across consumers and plans as well as the related but distinct facts that this was a new market and that consumers had no previous experience in it. Further, using detailed, individual-level panel data of actual choices in a complex, high stakes context will add to economists' understanding of consumer choice more broadly.

Our primary focus in this article is on whether Medicare Part D enrollees improved over time in terms of reducing overspending. We define overspending as the consumers' annual *ex post* out-of-pocket (OOP) costs for insurance and prescription drugs above the cost of the cheapest alternative, where the alternatives include other Part D plans as well as having no coverage. Analyzing changes in this aspect of choice alone is insightful given the high persistence in an individual's drug spending over time,[5] and our use of panel data eliminates the effects of individual-specific, time-invariant attributes, including risk aversion. In this article we exclusively focus on those who did not receive federal low-income subsidies in either year due to differences in Part D's design across income levels. Specifically, those with low-income subsidies can switch plans multiple times throughout the year,

---

[4] Choi, Laibson, and Madrian (2010) present experimental evidence that individuals pay more attention to some attributes than others when presented with multiattribute financial contracts. In contrast to financial contracts, beneficiaries of Part D may revise their enrollment and choice decisions on a regular basis. We are not aware of any existing evidence, experimental or otherwise, about whether such biases persist over time.

[5] See Pauly and Zeng (2004) for one recent example of this widely-documented fact for the Medicare population.

receive much larger premium supports, and they face small, regulated copayments for drugs on their plans' formularies. [6]

Our results provide robust evidence of large reductions in overspending from 2006 to 2007, with average reductions in overspending of \$298, which is 55% of the 2006 level. In addition to these large average effects, we find substantial heterogeneity, with 81% of the study population lowering their overspending. The greatest reductions were achieved by those who overspent most in 2006, and this cannot be explained by changes in health. Interestingly, the improvements were greatest among those age 85 and above, and those initiating medications for Alzheimer's disease in 2007 improved by more than average. Although we cannot observe the choice process itself, these two results suggest that populations with greater prevalence of cognitive limitations are helped by various sources, including family members, health care providers and other private organizations, and decision support tools such as online plan finders.

Switching plans was a primary source of improvement, although we also find evidence of improvement among those who did not switch plans. Our analysis of switching decisions reveals that consumers respond to financial incentives in deciding whether to remain in their current plan. Specifically, consumers' likelihood of switching increases greatly with their overspending in their current plan, indicating that their decisions incorporate past performance. Switching was also greater for those whose current plans would become more expensive in 2007 relative to the available alternatives, indicating that consumers factor in forward looking information as well. Finally, we find evidence that consumers' switching decisions depend on their individual-specific aspects of the levels and changes of their 2006 plans and not simply to readily observable factors that affect everyone equally, such as premiums.

---

[6] See Duggan et al. (2008) for a further discussion of these issues.

Figure 1. Overspending by Year
Using data described below, Figure 1 provides descriptive results for the changes in over-spending from 2006 to 2007. [7] During the initial year of the program most beneficiaries overspent by $300 to $500 dollars. The distribution of overspending has a long right tail, with a few beneficiaries overspending by more than $1,000. This results in the mean overspending, $547 dollars, being almost 40% larger than the median overspending of $393 dollars. More important, however, is the contrast between the two panels of this figure. In 2007, just one year into the program, the distribution shifts left, with substantially more beneficiaries closer to the cost-minimizing choice. Both mean and median potential savings in 2006 are cut in half in 2007, i.e., $251 and $185, respectively.

---

[7] This analysis does not control for additional sources of heterogeneity such as medical conditions, age, or others; however, the subsequent analyses in this article do. All variables are defined in the next section.

In the remainder of this article we further explore these descriptive results and their underlying causes. The article is organized as follows. Section 2 describes our data and how the key variables are defined. Section 3 evaluates how overspending changed between 2006 and 2007 overall, as well as the degree of heterogeneity in those changes across individuals in our sample. Section 4 reports how the changes vary with observed individual characteristics, such as overspending in 2006, age, sex, and levels and changes in health. In Section 5 we analyze the importance of various potential sources of improvement, including switching to better matching plans and changes in the chosen plan's design relative to changes in the minimum cost alternatives. We examine the switching decision in Section 6. Section 7 follows that with an analysis of the robustness under various alternative approaches. We conclude in Section 8.

2 Data

In this section, we first describe our data and compare the features of the plans included in our sample with the universe of Part D plans available. Next, we summarize how we generated each consumer's spending in each plan available to them in each year. With these estimates, we construct overspending, the key measure of plan choice in our analysis. Finally, we discuss the use of *ex ante* versus *ex post* drug consumption to evaluate improvements in overspending.

2.1 Study sample

Data from the Centers for Medicare and Medicaid Services (CMS), CVS Caremark (a pharmacy benefits manager, hereafter "the PBM"), and ancillary sources were used to estimate the cost of each plan to each patient in both 2006 and 2007. The PBM provided us with a large data set of its enrollees, for whom we observe their chosen plan with certainty, the universe of their claims,

whether and which subsidy level they received, and their gender, age and detailed measures of health status, described below.

Our study sample included 71,399 individuals who were enrolled in stand-alone Prescription Drug Plans (PDPs) provided or administered by the PBM for all of 2006 and 2007 and who did not receive a federal low income subsidy in either year. This sample excludes those not enrolled for the full year, as well as those who switched plans within the year, which this non-subsidy population could do if they moved between regions. Because our analysis required both years of data, we also cannot examine the decisions of those who switched into or out of the set of plans offered by the PBM. Likewise, we exclude those who switched into our out of a Medicare Advantage (MA) plan because we cannot measure an individual's costs for prescription drugs and prescription drug insurance in those plans because the premiums include both drug coverage and coverage for other types of health care. Among the population of 214,896 individuals that meet the other criteria for inclusion in our study, only 0.07% (i.e., 7 per 10,000) switched from an MA to a PDP from 2006 to 2007, while only 0.2% switched from a PDP to an MA plan from 2006 to 2007. Thus among this population, PDP and MA plans appear to function as separate markets, and excluding these few individuals from the sample will not meaningfully change the results.

An attractive feature of our data is that we observe individuals enrolled in PDPs that the PBM sells directly, under the SilverScript brand, and those in PDPs administered by the PBM but sold under different names. These administrative agreements between insurers and the PBM are rarely known to individuals and are likely to be unrelated to any important individual characteristics. As a result, our study sample incorporates not only those who chose a SilverScript plan but also those who in essence were randomly assigned to be administered by the PBM.[8] This includes nine different PDPs in 2006 and eighteen in 2007, where only about 19% of the sample was

_____

[8] Additionally, the PBM is prohibited from designing these other plans or negotiating prices for them; they may only administer the claims.

Table 1. Part D Plan Characteristics

	Plans in Study Sample			All Plans

Enhanced plan	0.50	0	1	0.49	0	1
Observations		258			1,804	

NOTE: The plan is identified by the plan ID, which is unique for each region.

enrolled in the SilverScript plans. Similar to all available plans, those in our sample vary greatly in their enrollment sizes.

Table 1 reports the characteristics of our study plans and those of all available plans. The changes in the means indicate that the plans in our study sample became relatively more generous in some aspects with relatively larger reductions in average premiums and deductibles, and greater increase in the prevalence of doughnut hole coverage for generics. At the same time, our study plans became relatively less generous on average with greater relative increases in the share of common drugs off the formulary or requiring prior authorization. In addition to these average changes, the 5th and 95th percentiles in Table 1 show that these changes over time varied across our study sample's plans. The effects of this heterogeneity across plans also vary across individuals based on their levels and types of prescription drug utilization.

Because our analysis focuses on overspending, and not spending per se, these differences in average changes have uncertain effects *a priori*. This occurs because mean plan characteristics

are irrelevant to the definition of overspending, which depends on the individual-specific levels of the actual and minimum-cost options alone. It also occurs because, for individuals in our study sample, all but one of the plans in our study sample represent other, non-chosen alternatives for 2006. Consequently, relative improvements by those non-chosen in-sample plans cannot reduce overspending, but rather can only increase it or leave it unchanged. Further, not all of the plans in our sample improved by more than average in terms of the sum of their premiums and deductibles. In Section 5 we evaluate the change in overspending for the subset of our sample enrolled in such plans.

The fact that our sample does not include any plans with doughnut hole coverage in 2006 may raise concerns about the generalizability of our results. For example, Abaluck and Gruber (2009) argue that an important reason why beneficiaries make mistakes in their enrollment decisions is their biased preference for plans that include doughnut hole coverage. That is, they conclude that once differences in other attributes such as premiums are included, plans with doughnut hole coverage are actually more expensive for most individuals who choose them than alternatives without doughnut hole coverage. Table 1 shows that in 2007, generic doughnut hole coverage was more prevalent among our study sample's plans as in the alternative plans. This occurred because the expansion of generic doughnut hole coverage among our study sample from 2006 to 2007 exceeded its growth among all PDPs. This change, coupled with the bias reported by Abaluck and Gruber, would cause us to *underestimate* the true magnitude of average reductions in overspending from 2006 to 2007 among the entire population enrolled in PDPs. We present additional evidence on this issue below in Section 5.

2.2 Measuring overspending

Our focus in this article is to evaluate how the chosen plan compares to the person's cheapest alternative, where we refer to the difference in the individual's costs between the two as "overspending".

To calculate this, we use data from the PBM on the individual's prescription drug claims, enrollment decisions, region of residence, and subsidy level in conjunction with CMS data on the characteristics of each plan available in each person's region in each year. These characteristics include premiums, deductibles, doughnut hole coverage, and formularies, which indicate what the beneficiaries' costs would be for every possible drug.

The total cost of each alternative for each person is the sum of the OOP prescription drug costs and the plan premiums. We provide extensive details about how the OOP prescription drug costs were calculated for each alternative in Appendix A. Briefly, we relied on the CMS formulary files to determine the copayment each individual would have paid for each drug he consumed under every PDP available in his region. When the formulary file provided a coinsurance rate, or when the individual was below the deductible or in the doughnut hole, we determined the relevant price in each plan from Wolters Kluwer Health data or from data collected from the CMS plan finder website.

Throughout the article, we consider "no insurance" as one of the options that individuals may choose, although we validate the robustness of the results when this option is excluded in Section 5. For the OOP prescription drug costs without insurance, we relied on the usual, customary price provided by CVS. For the main analysis presented in this article we assume a price elasticity of demand for prescription drugs of -0.54 to allow the total amount of drugs consumed by a beneficiary to vary under different marginal drug prices.[9] To check the sensitivity of the results to our elasticity assumption, we alternatively assumed perfectly inelastic demand, holding constant the total prescription drug consumption across all options at the level reported in our PBM data itself. These results are reported in Section 7.

---

[9] This is the drug price arc-elasticity estimate for Medicare beneficiaries obtained by Shea, Terza, Stuart, and Briesacher (2007). This is likely the most accurate estimate for this population, and it is more elastic than the other estimates. Using the most elastic estimate is likely to yield the lowest reductions in overspending from 2006 to 2007, as it reduces the amount of overspending. Our results using an assumption of perfectly inelastic demand confirm this, as shown in Section 7. We elaborate on the reasoning in the appendix.

2.3 *Ex ante* and *ex post* costs

One important decision in analyzing how consumers' choices change over time in a context with uncertainty is adopting a perspective on what information consumers use to make their decisions. Conceptually, consumers may rely on different levels of information with respect to uncertainty regarding future drug consumption. At one extreme, they may be fully myopic and utilize only their current consumption, ignoring the possibility of future changes when making choices about which plans to enroll in. At the other end, they may have perfect information and no uncertainty, anticipating precisely how future drug consumption will change and incorporating that into their choices of plans. Between those are intermediate cases, such as consumers being aware of probabilities and expenses of various potential illnesses and purchasing plans accordingly, but not knowing precisely whether or when they will acquire those illnesses.

All three of these cases are plausible. For both practical and conceptual reasons, in the primary analysis reported here we adopt the fully-informed approach in which consumers' choices for a given year are evaluated based on their actual drug consumption in that same year.[10] We refer to this as the *ex post* approach, while we refer to the other extreme as the *ex ante* approach. Conceptually important in our context, the *ex ante* approach eliminates the potential for learning, as consumers may have changed their drug consumption as they learned the intricacies of PDPs or gained familiarity with their own plans' formularies. These assumptions of the *ex ante* approach are rejected by Tchernis, Normand, Pakes, Gaccione, and Newhouse (2006), who present evidence consistent with consumers having private information regarding the evolution of their own health status. They find that consumers choose plans that are more generous for treatments which they might likely need in the near future. Practically speaking, we cannot rely on the *ex ante* benchmark to study within-person changes over time because we do not observe individuals' drug consumption

---

[10] This is the same approach taken by Fang, Keane, and Silverman (2008, §5) when comparing the *ex post* total medical expenditures under basic Medicare (parts A and B) with and without Medigap supplemental insurance.

in 2005. This precludes us from generating the 2006 cross-sectional estimates under this alternative approach, which are essential for evaluating the within-person changes over time. However, we compare the cross-sectional overspending results for 2007 from both the *ex post* and the myopic *ex ante* approaches in Section 7, and we find no notable differences between them.

2.4 Additional variables

The data provide several additional types of variables. First, the data provide health measures for each person at each point in time. These are defined by a proprietary system known as Ingenix Pharmacy Risk Group variables (PRGs) and their corresponding calculated risk scores. The PRGs are a vector of 126 indicator variables for whether drugs were consumed for specific clinical indications. These indicators do not vary with the quantity or cost of drugs taken for a condition, but rather they simply indicate whether the individual took any drugs for each of the conditions. From these, we generated dummy variables indicating whether the individual took medications in each of the 15 most common PRGs in our sample. These fall into 9 broader illness categories that we include as dummy regressors in the second column. They are, from more to less frequently observed: hypertension, cholesterol and other cardiovascular, pain, mental health, antibiotics, anticoagulants, thyroid conditions, diabetes and osteoporosis. We also include controls for a tenth illness, Alzheimer's disease, because of its link with cognitive impairment. The Ingenix risk scores are used by insurers to predict individuals' future prescription drug expenditures based on their prescription drug claims history and demographics. In our sample, the risk score has a mean of 5.1 and a standard deviation of 3.8. To give a sense of scale, taking medications for Alzheimer's disease increases the risk score by 2.8, while taking hypertension medications increases it by 1.4.

Second, the PBM data allow us to identify which individuals switched plans, which plans they switched to, which they switched from, and for those who switched, how they would have fared

in 2007 if they had stayed in their 2006 plans. Third, the CMS data provide details about how each plans' design changed over time as well as which plans exited and entered each region. While changes in a plan's premiums equally affect all individuals who do not receive low income subsidies, changes in other plan attributes, such as deductibles, doughnut hole coverage, and formulary design, have heterogeneous effects. We examine the implications of this heterogeneity on differences in the within-person changes in overspending in Section 4. Fourth, the data indicate the individuals' federal income subsidy status, allowing us to exclude all of those who ever received a subsidy, as well as their ages and sex. Sex is not reported for four individuals, so they are excluded from models that account for sex.

3 Within-Person Changes in Overspending

We begin by estimating first difference regressions of overspending for 2006 and 2007. Define ΔO_i as the within-person change in overspending for individual i, ΔH_i denotes a vector of variables for the within-person changes in the measures of health, specified above, and Δu_i are the changes in the idiosyncratic error. We estimate the following equation:

$$\Delta O_i = \alpha + \Gamma \Delta H_i + \Delta u_i. \tag{1}$$

The main coefficient of interest is α, which is interpreted as the average within-person change in overspending. In Table 2 we present estimates from four models to determine whether the results can be explained by changes in health. The first model does not control for changes in health, i.e., we exclude ΔH_i, but the second model does. In the third and fourth models, we analyze only the subset of consumers with stable health, which we define in two alternate ways. In the third column, we define people in stable health if their total risk score changed by less than 0.5. In the fourth column, we further required that they did not change for any of the ten individual conditions that

we include. In the most basic model, average overspending was reduced in 2007 by almost $300, i.e., a reduction of 54% of the average overspending of $546 in the regression sample in 2006.

To show the degree of heterogeneity in the change in overspending, we also report various points in the distribution of the unadjusted within-person change for the sample included in each regression model. The bottom half of the table demonstrates the large amount of heterogeneity in these improvements. Overspending fell for 81% of the sample, with improvements ranging from a few dollars up to amounts exceeding $1,000. While 19% overspent more in 2007 than in 2006, the absolute value of their increases ($224) amounted to only slightly over half of the average decreases experienced by the 81% who improved ($419).

The remaining columns of Table 2 indicate that these results are largely invariant to changes in individual health, with similar means and distributions of improvements across all four columns. The results in the second column are conditional on changes in individual's health. These show slightly larger reductions than the unconditional changes, with mean improvements of $298, or %55 of the 2006 mean. Because of concerns about changing health in explaining our results, in the remainder of this article we continue to analyze both the full population conditional on changes

in health, and the subset of those in stable health. Given the similarity of results with our two definitions of stable health, as shown in the third and fourth columns of Table 2, we rely on the more inclusive one (in column three) because of its larger sample size.

These results highlight the importance of analyzing how choices evolve over time, particularly in a new market, which itself was evolving to provide better information to consumers, and in which consumers have no prior experience. The (unconditional) mean overspending in 2006 by our regression sample was $546, i.e. a mean overspending of 36.5% percent of the total out of pocket costs. However, in 2007 overspending averaged 21.6% of total out of pocket costs, amounting to a 41% reduction in only one year. The results show that reductions in overspending are independent of changes in individual medical conditions, but even among those in stable health the improvements vary substantially. In the next section, we analyze how 2006-2007 changes in overspending varied with other observable patient characteristics.

4 Differences in Improvement by Observed Individual Characteristics

To investigate what explains the substantial degree of heterogeneity in improvement, we begin by expanding the basic model used in the previous section to consider how the within-person changes vary by observed individual characteristics. Specifically, we estimate

$$\Delta O_i = \alpha + \Gamma \Delta H_i + \beta X_i + \Delta u_i, \tag{2}$$

where X_i includes a vector of observed time-invariant characteristics for individual i, and the remaining variables are as in equation 1. By including X_i, in these models we allow the within-person change in overspending to vary with observed individual characteristics, including age in 2006 (65-69, 70-74, 75-79, 80-84, and 85 and above), health (the 2006 risk score, and indicators for whether the person took medication in 2006 for each of the 10 individual illnesses), and sex.

In general, these coefficients provide evidence about the equity of Part D's current design by indicating whether some groups improved less, or even worsened, from 2006 to 2007. For example, the coefficients on age and on the levels and changes in taking medications for Alzheimer's disease provide evidence about whether the improvements were smaller among populations where cognitive impairment was more prevalent.[11] In a second version of the model, we also include in X_i a set of categorical variables for the extent of overspending in 2006 (less than \$100, \$100-\$200, \$200-\$300, \$300-\$500, \$500-\$1,000, \$1,000-\$2,000, more than \$2,000). This provides evidence about whether overspending in 2006 persisted through 2007, or whether those who overspent most in 2006 also improved most in 2007. In a third version of the model, we also control for the level and change in gross drug spending in the actual plan, defined as the total of the amount spent on prescription drugs by the individual and the plan on the individual's behalf. Including these two additional variables provides evidence about whether any difference by 2006 overspending or the health measures are simply due to differences in total drug consumption.

Table 3 presents the results from these three first difference models. As before, we also estimated models on the subset in stable health but we do not report them given their similarity with the other results shown in Table 3. The results show that the change in overspending varies substantially with these observed characteristics. Improvements were greater for females and for those who were older, with those age 85 and above reducing overspending by \$93 to \$108 more than those age 65-69. Given the inclusion of categorical dummy variables in these models, the intercepts in these models indicate the expected within-person change among those in the omitted groups. For example, the results from the second model show increases in overspending of \$295 for females

---

[11]To substantiate this interpretation, a recent review article on Alzheimer's disease in *The New England Journal of Medicine* characterizes it as "a deterioration of memory and other cognitive domains" that is "the most common form of dementia, accounting for 50-56% of cases at autopsy and in clinical series." The article continues by citing previous work showing that, "The incidence of the disease doubles every 5 years after 65 years of age ...," and, "... the odds of receiving the diagnosis of Alzheimer's disease after 85 years of age exceed one in three," Querfurth and LaFerla (2010).

age 65-69 who overspent by less than $100 in 2006, had the average level and change in risk score, and did not take or initiate medications for any of the 10 most common illnesses.

The results also show that initiating medications for some of the most common medical conditions in 2007 led to significant reductions in overspending. Results from the second column indicate that beneficiaries who began treatment for hypertension, anticoagulants, osteoporosis and Alzheimer's reduced their overspending from 2006 to 2007 by $22, $37, $27 and $50 more than average, respectively. Further, the within-person changes in overspending among those who were taking medication for Alzheimer's in 2006 did not significantly differ from those not taking these medications. This, in conjunction with the results by age and the results showing that those who initiated medication for Alzheimer's in 2007 improved by more than average indicates that other people are likely helping these populations choose plans. Although we cannot distinguish between the various plausible explanations, among them is that the new diagnosis of a condition such as Alzheimer's disease triggers greater involvement of family members and health care providers in the choice of prescription drugs and drug insurance. As shown in the third column, these results are not simply reflecting levels or changes in total drug consumption, as they persist even conditional on that, and in fact the estimated improvements by those who initiated medication for Alzheimer's disease are even larger.

The last two columns of Table 3 show a final set of important differences in within-person changes in overspending. Relative to those with overspending below $100 in 2006, all other groups of beneficiaries reduced their overspending substantially more. These reductions increased monotonically with the size of the 2006 overspending, with those overspending by more than $2000 reducing their overspending by an average of $2953 to $3173 more than those who overspent least in 2006. These results provide some evidence that individuals incorporate past performance in their current choices.

5 Sources of Improvement

In this section, we explore what explains the reductions in overspending from 2006 to 2007. Several potential sources of these improvements exist, including changes in plan design and the available plans, changes in health, learning about plans' specific formularies, and consumers' decisions to switch plans.

Figure 2 illustrates and compares the gains by switchers and non-switchers, with results analogous to Figure 1. The top two panels, which report the overspending by year for switchers, indicates that switching was a primary contributor to improvement: in 2006, the distribution of overspending has a thick right tail with a mean of $579. In 2007, however, those who switched overspent by an average of $147, and the distribution becomes highly concentrated on the left, with half of switchers overpaying by $82 or less in 2007. The two bottom panels of Figure 2 make

evident that even non-switchers overpaid less in 2007 than in 2006. In 2007, beneficiaries who stayed in their 2006 plans reduced their mean overspending from \$509 to \$375. Finally, the figure also indicates that those who chose to switch had higher overspending in 2006 than those who did not. We explore this issue more in detail in Section 6.

To further analyze the effects of switching, we estimate two models. The first is identical to equation (1) except that we also allow the change from 2006 to 2007 to vary with whether the person switched or not, denoted as S_i.

$$\Delta O_i = \alpha + \Gamma \Delta H_i + \theta S_i + \Delta u_i. \tag{3}$$

The second is identical to equation (2) except that it includes S_i,

$$\Delta O_i = \alpha + \Gamma \Delta H_i + \beta X_i + \theta S_i + \Delta u_i. \tag{4}$$

As reported in Table 4, the results conditional on individual characteristics are similar to the changes in the unconditional means shown in Figure 2. Non-switchers reduced their overspending from 2006 to 2007 by \$137 on average, while switchers averaged an additional \$299 reduction, for a total decrease of \$435. As the results from the full models in second and third columns indicate, even when the change is allowed to vary with a number of other observed characteristics, the difference between switchers and non-switchers is \$232-233. Thus, switching was a primary source of improvement.

A comparison of the results for the other variables in the models reported in Tables 3 and 4 shows how switching moderates the other observed differences in the magnitude of the within-person changes from 2006 to 2007. Interestingly, the large differences across the 2006 overspending level remain, indicating that they exist for reasons in addition to differences in the choice to switch plans itself, which we investigate in the next section. Similarly, the larger reductions in overspending

by those who initiated medication for hypertension, anticoagulation, osteoporosis and Alzheimer's disease remain even conditional on switching. Finally, the results suggest that switching decisions fully explain the differences observed by age and sex.

We conduct an additional analysis to understand the extent of improvement among non-switchers that was due to changes in plan design, plan availability, and drug prices. To accomplish this, we re-estimate equation 1 but hold individuals' drug consumption constant at their 2006 levels. Specifically, we first simulate each person's 2007 spending using his 2006 claims in conjunction with each option's 2007 attributes and drug prices. We then define the within-person change in overspending for this analysis as the difference between this value and the 2006 overspending, which we define as before. Under this approach, any changes in overspending from 2006 to 2007 are due entirely to changes in the premiums and cost of drugs in the individuals' actual plans and their minimum-cost options. [12]

The results from this model show that when only plan design and availability and drug prices are allowed to change from 2006 to 2007, non-switchers reduced their overspending by $117, which is 85% of the total reductions conditional on changes in health shown in Table 4 column 1.[13] Thus, improvement in their own plans that they chose to remain with, relative to the changes in the minimum-cost options available to them, explains a large share of improvement among non-switchers. The remaining 15% is due to changes in drug consumption not accounted for by changes in the measures of health included in the model. One potential source of such changes is consumers learning how to navigate their plans' formularies in ways that reduced their spending on their actual plan more than their minimum-cost plans, e.g., due to differences in the formularies.

---

[12] As before, we assume a price elasticity of demand for drugs of -0.54, although the results are virtually identical when we instead assumed perfectly inelastic demand.

[13] The effects of changes in the minimum cost plans' designs are ameliorated by our inclusion of no insurance in the choice set, which had a stable design by definition. However, this option is particularly affected by secular increases in drug prices, since without insurance the individual would pay all of those higher costs.

The estimates of the switching decision presented in the next section provide additional insights about whether these reductions by non-switchers should be viewed as passive or active.

We implement one final analysis to consider the role of plan design in explaining the gains by non-switchers. Specifically, Table 1 shows that on average, our plans improved by more than the average PDP in terms of reduced premiums and deductibles. However, among our study sample, 9,670 non-switchers were enrolled in plans that improved by less than average, in terms of the change in the sum of the plans' premiums and deductibles. As indicated in Table 1, the average improvement in this measure for all PDPs was $12.56. Re-estimating equation 1 for this sample shows they experienced an average reduction in overspending of $182, which is larger than the average improvements by non-switchers in our full sample, as shown in the first column of Table 4. Thus, the relative reductions in the average premiums and deductibles by our study plans do not explain the improvements by non-switchers.

6 The Switching Decision

To analyze individuals' decisions about whether to switch plans, we estimate the probit model

$$S_i = \alpha + \Gamma \Delta H_i + \beta X_i + \epsilon_i, \tag{5}$$

where, as above, ΔH_i is the change in health status, and X_i is a vector of time-invariant individual characteristics including health status and age in 2006, among others. X_i also includes the category of the individual's overspending in 2006, which indicates whether those who overspent more in the previous year responded to these financial incentives by switching to other plans. Also within X_i is a variable that indicates how the person's 2006 plan changed in 2007 relative to the alternatives, i.e., it is defined as the difference in the person's 2006 plan's percentile ranking in 2006 and 2007. By capturing how much worse the individual's 2006 plan would become in 2007 relative to the

available alternatives, this variable provides insights about whether people were forward looking in their plan choices or whether inertia causes consumers to remain in their plans despite those plans growing relatively worse over time. The error term ϵ_i is normally distributed. We estimate this model on the full sample and on the sample in stable health.

We also estimate these switching models with an additional vector of 2006 plan fixed effects,

$$S_i = \alpha + \Gamma \Delta H_i + \beta X_i + \Psi P06_i + \epsilon_i. \tag{6}$$

The results from this model provide insight on two additional issues. First, the 2006 plan fixed effects eliminate any plan-specific attributes that affect the probability of switching out of the plan. These plan attributes include both the levels and changes of the 2006 plan to the extent that they influence switching decisions. By comparing within-plan differences in switching decisions, we can determine whether they depend on the individual-specific aspects of their 2006 plans. For example, the backwards-looking 2006 overspending levels as well as the forward-looking change in the 2006 plan's percentile ranking in 2007 include both an individual component and a plan average component (e.g., levels and changes in premiums). In this model, the coefficients on these variables indicate whether people respond to the individual-specific aspects. Second, by evaluating the within-plan differences, these results mollify concerns that our switching results are driven by non-generalizable aspects of the plans in our study.

Table 5 presents the average marginal effects from these probit estimates. As suggested by the results in Table 4, the switching decisions differ with observed characteristics, with males 14 percentage points less likely than females, and the oldest group 39 percentage points more likely to have switched plans than those age 65-69. These results are conditional on health and the magnitude of overspending in 2006. Consequently, they reflect differences in how the decision for 2007 was made, rather than differences in incentives or experience *per se*. The effects of the

level of health status on switching also suggest that the re-enrollment decisions did not vary with experience, as captured by the number and types of conditions for which medications were taken. The probability of switching varied with the presence of a medical condition by up to 6 percentage points, with people with any of 8 individual conditions significantly less likely to switch plans. In contrast, greater prevalence of other illnesses captured by the risk score was associated with higher probability of switching, although those effects are small as well. Individuals who initiated medication for new conditions in 2007 are slightly less likely to switch plans. Although these effects are generally small, they range up to 10 percentage points for mental health and five of the ten achieve a significance level of $p < 0.05$.

One bias that is commonly cited in the behavioral economics literature is inertia. The estimated marginal differences across the 2006 overspending categories show that the probability of switching plans jumps quite significantly for those whom 2006 overspending was between \$200 and \$300 a year, and switching is substantially higher yet at levels above \$300. Previous studies have documented poor choices during the first year of Part D, leading researchers to conclude that consumers could not choose well in this context and additional reform was needed, such as reducing the number of plans available. Due to these dynamic aspects, our results indicate that the partial-equilibrium static approach underlying such proposed reforms are incomplete: overspending as small as \$25 per month (\$300 per year) in 2006 resulted in a 49 percentage point increase in an individual's likelihood of switching into a new plan for 2007.

In addition to these results by overspending category showing that switching increases sharply even at the lower levels of overspending, we offer evidence about inertia by examining whether switching depends on how the person's 2006 plan changed in 2007. The large positive effect of this variable indicates that beneficiaries tend to switch out of their 2006 plans if those plans would become more expensive in 2007 relative to the alternatives available to them. Specifically, the results show a 7.7 percentage point increase in the likelihood of switching for each additional ten

percentage points that the 2006 plan worsened in the individual's distribution of options available in 2007. In addition to assuaging concerns that inertia is dominant in this market, this result indicates that consumers incorporate some forward-looking information in their choice of plans, as these results are based on within-plan changes in performance and are conditional on the level of overspending in 2006.

The results can also be naturally interpreted as showing who was more likely to remain in their 2006 plans. Specifically, the results indicate that those most likely to remain in their 2006 plans, conditional on other factors, were precisely those who overspent least in 2006, and those for whom their 2006 plans would improve most in 2007, relative to the alternatives. For example, those whose 2006 plans would improve by ten percentile points in their distribution of alternatives in 2007 were 7.7 percentage points less likely to switch out of that plan.

The results in the final column of Table 5 indicate that switching decisions depended not only on plan-level factors but also on the individual-specific factors that affected overspending and future changes in the plan's relative costs. The number of observations for these estimates is slightly smaller, as the estimates exclude individuals in plans that had no within-plan variation in the switching decisions for the individuals in our sample. These results show that overspending levels above $1,000 led to significantly higher levels of switching relative to those in the same plan who overspent less in 2006. Similarly, those for whom the plan would become relatively worse for in 2007 were also more likely to switch out than others in the same plan. The results for the other coefficients also maintain their general size and significance, showing that they, too, are not driven by plan-level factors.

7 Robustness of Results

In this section we consider whether the results for the mean within-person changes we have reported are robust to alternative approaches. First, we replicate the analysis but adopt the assumption that demand for prescription drugs is perfectly inelastic, rather than assuming an elasticity of -0.54 as in our main results. Second, we replicate the results but use the actual spending for the actual plan. In the main results we relied on the simulated spending for the actual plan to be consistent in our approach across the entire choice set. Third, we evaluate within-person changes in overspending when we exclude no insurance as an option from the choice set. Fourth, we evaluate within-person changes in overspending on prescription drugs, excluding premiums. This final analysis was implemented to determine whether the relative improvements in our plans' premiums, as shown in Table 1, explain the mean within-person changes we have observed.

For each of these versions, we estimate two models. The first is identical to that reported in Table 2 column 2, showing the average within-person change conditional on changes in health. The second is identical to that in Table 4 Column 1, which are also conditional on changes in health but allow the within-person change to differ between those who switched plans and those who did not.

For comparison, the main results are reported in Panel A of Table 6. The approach behind these results allowed for a quantity response to the prices of drugs under each available alternative. To test the sensitivity of the results to this assumption, we replicate many of the analyses assuming perfectly inelastic demand for drugs. The results, reported in Table 6 Panel B, indicate somewhat larger average improvements than under the assumption of elastic demand. Specifically, here the reductions of overspending are $369. As a percent of the mean 2006 overspending, this amounts to a 46% reduction, which is slightly below the 54% found for the elastic results. The results

by switching show somewhat larger improvements for those who did not switch but $112 greater improvements for those who did, compared with the main results. [14]

Table 6 Panel C shows the results when we use the actual spending in the actual plan instead of the simulated spending in the actual plan. These results are largely similar with our main results, showing slightly smaller reductions in overspending from 2006 to 2007. In Panel D we show the results when no insurance is excluded as an option. These results show just slightly larger reductions in overspending than in our main results, which include no insurance.

———————————————————

[14] Although we do not report them in the table, the remainder of the key implications of the main results also persist.

In Panel E, we show the results when evaluating only the change in overspending excluding premiums, i.e. considering only consumers' OOP spending on prescription drugs. Based on this measure, the results also show substantial average reductions in overspending from 2006 to 2007. This indicates that the relative reductions in premiums shown in Table 1 do not fully explain the average improvements we observe.

As a final consideration of the robustness of our results, we compare the 2007 cross-sectional results using both our primary *ex post* approach with those from the alternative *ex ante* approach. All of the preceding analyses adopt an *ex post* benchmark by considering overspending based on the actual drug consumption for the year following consumers' decisions about which plan to join. To determine whether the results depend on this assumption, here we alternatively assume that consumers' only relied on their 2006 drug consumption when making their enrollment choices for 2007. To do so, we generate the total *ex ante* 2007 spending by combining the patient OOP costs from their 2006 drugs with the 2007 attributes of each available alternative such as the plans' formularies and premiums. Because we lack information on individuals' 2005 drug claims, this analysis is limited to comparing the cross-sectional results for 2007 from these two alternative assumptions about consumers' information sets. The results in Table 7 indicate great similarity between the two approaches, both in terms of the mean as well as at various other points in the distribution of 2007 overspending. In addition to this high degree of similarity, the results show that overspending is somewhat lower using the *ex post* benchmark rather than the *ex ante* approach.

8   Conclusions

We analyzed Medicare Part D plan choices of older consumers who faced a potentially dizzying array of options for complex, multiattribute products. Despite these features raising concerns for widespread consumer confusion, we found evidence that overspending fell substantially on average,

Table 7. Comparing 2007 Overspending Using *Ex Ante* and *Ex Post* Prescription Drug Claims

	Ex Post Using 2007 Claims ($)	*Ex Ante* Using 2006 Claims ($)
Mean	251.0	298.4
Median	184.8	197.8
5th Percentile	0.0	0.0
10th Percentile	1.7	14.0
25th Percentile	65.0	79.1
75th Percentile	184.8	345.9
90th Percentile	515.7	526.8
95th Percentile	682.9	700.5

NOTE: The *ex ante* approach defines the total spending in each available plan in 2007 using the claims filled by the person in 2006. The *ex post* approach uses the claims filled by the person in 2007. Both rely on the plans available and their attributes (e.g., premiums and formularies) in 2007.

and for a large share of the population, even after less than a full year of experience in this new market. Specifically, we found that the mean cost difference between individuals' actual choices and their cheapest options fell by about $300 from 2006-2007, and the median difference fell by about $240. Over 80% of our study population experienced reductions in overspending, with the greatest reductions among those who overspent the most in 2006.

We find evidence that this reduction in overspending is due to changes by individuals as well as changes in plan design and availability. Those who switched plans reduced their overspending far more than those who did not. The likelihood of switching plans for 2007 increased substantially with the amount of overspending in 2006. This result contrasts with well-known evidence of inertia, in which the levels of prior overspending were not associated with differences in the likelihood of changing gym membership choices (DellaVigna and Malmendier (2006)). In addition to incorporating backwards-looking information in individual's spending, our results show that the likelihood of switching out of a plan was also higher when the current plan's relative costs were set to increase in the next year. Finally, our results show that switching depended not only on readily-visible plan attributes that affect everyone, but also on how the plan's traits affected them individually, relative to their average effects.

Our results also show that even those who did not switch plans improved on average, due largely from changes in the design of their plan relative to the design of the cheapest options available to them. However, these results should not be interpreted as passive gains: as indicated by our estimates of the decisions to switch out of their 2006 plan, those who chose to remain were those who overspent least in 2006, and those for whom the 2006 plan was set to improve most in 2007, relative to the alternatives. Additional research evaluating consumers' and suppliers' decisions would provide a deeper understanding of the dynamic relationships between the two.

The richness of our data allowed us to consider how the within-person changes varied across a number of individual characteristics. Notably, our results provide no evidence that populations with greater prevalence of cognitive limitations, as indicated by taking medications for Alzheimer's disease or being age 85 or above, improved by less than average. In fact, the oldest consumers improved by the most, those initiating medications for Alzheimer's disease in 2007 improved by more than average, and those taking such medications in both years did not significantly differ from the average improvement. These results suggest that these populations are assisted by various real-world institutions. These include children and other relatives, medical personnel, social networks, and other organizations and decision support tools. By evaluating actual choices, our analysis incorporates these institutions in ways that the previous survey- and laboratory-based research has not (e.g., Hanoch et al. (2009)).

Omitted from our analysis are risk aversion and uncertainty, although evaluating within-person changes over time accounts for them as long as their individual-specific effects are time-invariant. While these data offer a number of strengths, they can provide insights about only a limited scope of choices related to Part D. First, because our data include only enrollees, we cannot analyze the participation decision itself, as done by Heiss et al. (2007). Second, we analyze the choice of prescription drug insurance in isolation, where Medicare beneficiaries face a number of decisions about how to acquire insurance for the full range of medical care. Thus, some individuals

may improve in their choices in Part D plans, but not improve along these broader decisions about health insurance coverage overall. Unfortunately, it is currently infeasible for researchers to analyze these broader decisions.

Our results add to the accumulating evidence that Part D represents a successful implementation of a market-based approach to deliver a large scale entitlement program (Goldman and McFadden (2008)). In addition to the high enrollment found by Joyce et al. (2009), Duggan et al. (2008) report that Part D has reduced pharmaceutical prices, increased the utilization of prescription drugs, and reduced medical expenditure risk, all at a substantially lower cost for the government than initially expected. Furthermore, although Heiss, McFadden, and Winter (2006) initially questioned whether a government run program could have more effectively controlled for the cost of drugs, they later concluded that Part D has been a tactical success that has induced high enrollment levels, ensured competition among private insurance sponsors, and kept drug prices and rates of consumer deception low (Heiss et al. (2007)).

One implication of our results for research on Part D specifically is that dynamic analyses that incorporate experience, market responses, and institutions and individuals that provide decision support yield different insights from cross-sectional analyses. As Part D has developed, consumers have had greater access to information through plan ratings, user-friendly websites, and software applications of pharmacy chains and other institutions to help people choose well-matching plans. However, these sources of information did not appear overnight when Medicare Part D was first implemented.[15]

Repeated evidence that choice overwhelms consumers and leads to poor matches between consumers and products will provide a partial economic rationale for policies such as strengthening

---

[15] See http://www.medicalnewstoday.com/articles/57318.php for one example of a private sector initiative that was not available in 2005 for the 2006 open enrollment but was available in the fall of 2006 for the 2007 open enrollment period. The plan finder offered through CMS was also overhauled between the two periods to be more user friendly.

consumer protection rules or mandating simplified retirement plans, credit cards, mortgages, or health insurance contracts. Alternatively, evidence that consumers capitalize on the heterogeneity of available products would indicate that policies that reduce barriers to entry and promote competition will enhance welfare. The existing evidence suggesting that consumers are unable to choose their health insurance plans appropriately has been obtained almost entirely from cross-sectional data that often abstracts from the actual choice process, e.g., by conducting surveys of financial literacy or familiarity with Part D Plan attributes. Our results, obtained by analyzing how a large number of consumers' actual choices evolved over time, provide some contrast. These differences highlight the importance of incorporating market dynamics and various sources of decision support in analyzing consumer choices.

APPENDIX

A Individual's Out-of-Pocket Costs for Each Available Plan and Year

For each person in each year, we estimated the total out-of-pocket (OOP) costs (the sum of plan's premiums and OOP prescription drug costs) for all PDPs available in the person's market. The Geographic Locator File from CMS was used to determine each person's PDP region code at each point in time. We then used the CMS Plan Information file to determine which plans were available in each person's market.

To generate the OOP and gross prescription drug costs for each person in each available PDP, we used the PBM claims data, which include all claims paid by the PBM as well as all of the claims submitted but rejected. We combined these with the CMS formulary files. Across all plans we held constant whether the prescription was filled via mail service or retail, and for retail prescriptions we assumed that they were filled at a preferred network pharmacy. This was essential because within a given plan, prices for a given drug can vary by pharmacy type (mail *vs.* retail) and whether the pharmacy is in the plan's network.

In the main estimates reported in the article, we allowed the consumption bundle to vary with the average price of the person's drugs in each plan. Starting from the amount consumed under the actual, chosen plan, we compute the amount of each drug consumed by applying the assumed arc-elasticity of -0.54 (from Shea et al. (2007)) to the difference in prices of each drug under the different formularies.[16] We then multiply this adjusted quantity by the individual's average price of prescriptions in each plan and add the appropriate premium for each plan.[17] This creates each plan's total OOP cost to each patient for each year, which we use to analyze how the chosen plan compares to the cheapest alternative.

One challenge to researchers examining consumers' actual Part D plan choices is that the CMS formulary file does not provide all required information in cases where patients paid the

---

[16] Because we define each option's costs based only on the drugs that were purchased under the actual plan, we are not able to fully incorporate substitution patterns among drugs, which may perhaps led to measurement error. For example, assume that drugs A and B are perfect substitutes, and in the person's actual plan they pay $10 for drug A, which they consume because the copay for drug B is $30. If in an alternative plan drug A's copay is $30 but drug B's is $10, the individual's total drug consumption and total costs would have remained unchanged. Under the assumption of perfectly inelastic demand, we would estimate the person's expenditures to be $20 higher per prescription under the alternative plan. Allowing for somewhat elastic demand incorporates some but not all of the demand response and thus gets closer to the true counterfactual drug spending. Unfortunately it is not feasible for us to estimate the impacts of specific formulary designs on consumption patterns in a more precise way.

[17] One unique characteristic of our data is that they identify which of the four federal low income subsidy (LIS) levels, if any, was received by each person in each year. This allowed us to eliminate the population who received any of the levels of low income subsidies in either 2006 or 2007.

full cost, as under the deductible or doughnut hole, or some fraction of it, as with coinsurance. Specifically, the formulary files do not provide the underlying prices of each drug in each available plan to which the coinsurance would be applied.[18] We relied on a range of data sources to provide these underlying prices. First, we used Wolters Kluwer Health Source LX claims data to generate an average price per unit (e.g., day's supply) for each of the Food and Drug Administration's National Drug Code (NDC) in each plan by quarter, region, and pharmacy type (retail or mail service). To do this, indicators in the Wolters Kluwer Health data were cleaned and used to generate these measures at the level of the PDP parent company. Individual plan identifiers are not available in these data, but the prices we need do not vary across plans within a parent organization, which we confirmed by examining "scraper" data from the Medicare Prescription Drug Plan finder website for 2006 as in Simon and Lucarelli (2006). These scraper data captured the price per unit for 400 common drugs for each plan in 2006.

Because the WKH data did not provide all of these underlying prices needed to estimate costs for each person in each available plan, we relied on the scraper data for most of the additional prices. Where needed, we multiplied the coinsurance rate by the average unit price from either of these two sources for the given NDC, quarter, region and pharmacy type.[19] To validate this approach of determining each person's total OOP spending in each available plan, we compared the total spending for the person's actual plan derived from this simulation method with that directly observed from the PBM data. The correlation coefficient between these was 0.81 in 2006 and 0.77 in 2007. This suggests that our method for estimating spending in counterfactual plans was highly accurate.

We also included not enrolling as a possible option to the choice set. One benefit of including this alternative is that it limits the extent to which any observed improvements in plan choice can be ascribed to exit or redesign of the lowest-cost plans. For this "no insurance" option, premiums were $0 and drug costs were determined by the usual and customary price, which is what the pharmacy would have charged a cash-paying customer.

---

[18] CMS began reporting such prices for a subset of National Drug Codes (NDCs) for the 2009 data but does not plan to release them for earlier years.

[19] Where necessary, for a given NDC we imputed these values by relying first on adjacent quarters, then on adjacent regions, and moved farther away in geographic or temporal space. For mail service pharmacies, where necessary we also imputed from retail pharmacies in the same region and quarter. Any remaining needed prices were imputed from the PBM data by dividing the price for the person's actual PBM plan by the average relative price for a given plan in the scraper data.
